## Abstract

Search for new physics with final states containing a same-sign dilepton pair at a center-of-mass energy of 13 TeV with the CMS detector

by

David McAlister Barry

Two related searches for Standard Model and beyond the Standard Model physics with a final state containing a pair of same-charged leptons and jets are performed using a sample of  $\sqrt{s} = 13$  TeV data corresponding to an integrated luminosity of  $137 \text{ fb}^{-1}$ , collected by the CMS detector between 2016 and 2018. The first inclusive search observes no excess above the Standard Model and thus places constraints on R-parity violating and R-parity conserving supersymmetric models with pair production of gluinos and squarks. Gluino masses are excluded up to 2.1 TeV, while top and bottom squarks are excluded up to 0.9 TeV. The second search measures the cross-section of the production of four top quarks within the Standard Model using both cut-based and multivariate approaches. The observed (expected) significance of the multivariate approach is 2.6 (2.7) standard deviations, with a measured cross-section of  $12.6^{+5.8}_{-5.2} \text{ fb}$ , consistent with the Standard Model prediction of  $12.0^{+2.2}_{-2.5} \text{ fb}$ . These results are translated into constraints on the Yukawa coupling of the top quark, as well as constraints on heavy scalar or pseudoscalar production in a type II 2HDM scenario.

## Introduction

### 1.1 Info

Some facts

- Standard model missing some stuff
- LHC smashes protons together very fast
- CMS detector is very big
- Analyze CMS data to find stuff beyond the standard model (e.g., SUZY)
- Did not find anything

The results presented in this thesis correspond to the published results in Refs. [1, 2, 3, 4]

# Appendix A

## Appendix Title

### A.1 Toy profile likelihood

This section presents an introduction to the profile likelihood method (used for the statistical results of this thesis) with a concrete toy example. The toy example consists of one signal, one background, and one shape-based nuisance parameter. Complete details of the method are in <https://arxiv.org/pdf/1503.07622.pdf> and <https://arxiv.org/pdf/1007.1727.pdf>.

#### A.1.1 Terminology

Bayes' theorem can be stated in a more applicable way as

$$p(k|D) = \frac{p(D|k)p(k)}{p(D)} \tag{A.1}$$

where  $p(A|B)$  is the (conditional) probability of A given B. Here,  $k$  represents a model, which consists of a set of parameters (parameters of interest, as well as annoying/nuisance parameters). Typically, the single parameter of interest is a signal “strength”  $\mu$  (how

much signal is there?), and a set of (many) nuisance parameters technically specified as a vector  $\vec{\theta}$ , but often just  $\theta$ . The posterior probability distribution function (pdf),  $p(k|D)$  is the distribution of parameters given the observed data  $D$ . The **likelihood**  $p(D|k)$  gives the likelihood of getting some data  $D$  given a particular model encoded in  $k$ .  $p(k)$  is a prior distribution of models, often taken to be “flat” in  $\mu$ . Lastly, the overall constant  $p(D)$  is ignorable when dealing with differences in likelihoods. This sets the stage for the toy example, which clarifies the meaning of the word **profile**.

### A.1.2 Toy example

Figure A.1 shows a toy distribution of jet multiplicity for background, signal, and data. The background component also contains a systematic uncertainty band corresponding to a shape nuisance parameter. This shape nuisance parameter prefers to increase yields at higher number of jets.

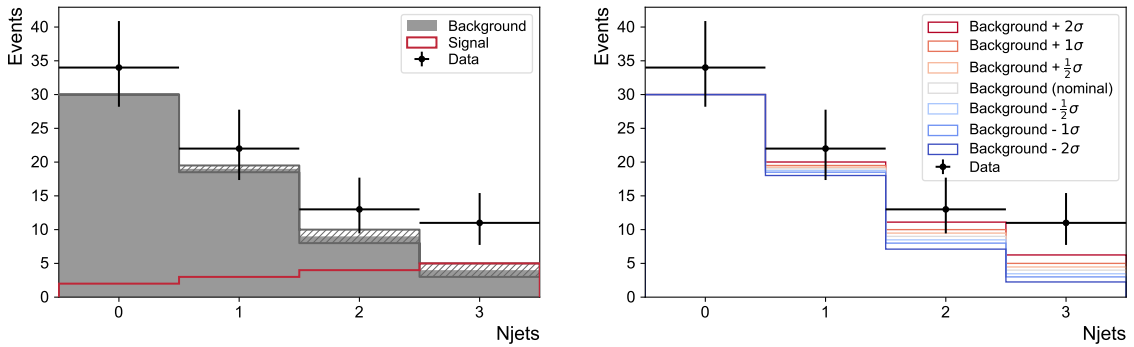

Figure A.1: Toy distribution (left) and single shape nuisance variation on background component (right)

As an intermediate goal to most statistical results/interpretations of the data, we want to compute the likelihood which will be a 2D function of the signal strength  $\mu$  and the value of the systematic variation  $\theta$ .  $\theta = 0$  will give the normal background yields, while  $\theta = -1$  and  $\theta = 1$  will give the  $1\sigma$  down and up variations, respectively. From

above,  $\theta = 1$  will absorb the signal, as it increases the background yield at high number of jets.

The likelihood function is the binned probability to get the data from a b or s+b poisson distribution, accounting for the pdf probability of nuisances  $\theta$ :

$$\mathcal{L}(\text{data}|\mu, \theta) = \prod_{j \in \text{bins}} \frac{(\mu s_j + b_j)^{n_j}}{n_j!} e^{-(\mu s_j + b_j)} p(\theta) \quad (\text{A.2})$$

here  $n_j$  represents the data count in bin  $j$ ,  $b_j$  the background count, and  $s_j$  the signal count. Technically,  $b_j$  is a function of  $\theta$ ; that is,  $b_j(\theta)$  depends on the value of the systematic variation where  $b_j(0)$  is the nominal background yield.

The goal is find maxima in the likelihood scan. Numbers can get very large given the factorial and the exponential. Since the  $\ln$  function is monotonically increasing, to make things numerically tractable and simpler, we the (negative) log since minimization problems are easier than maximization.

$$-\ln \mathcal{L} = - \sum_{j=0}^3 [n_j \ln(\mu s_j + b_j) - \ln(n_j!) - (\mu s_j + b_j) + \ln(p(\theta))] \quad (\text{A.3})$$

Even though it won't matter in the end (since we ultimately care about relative differences in the likelihood) note that  $\ln(n_j!)$  is just  $\sum_{i=0}^3 \ln(i)$  and it is independent of  $\mu$  and  $\theta$ , so it can usually be pre-computed.

We can then calculate likelihood values over the  $\mu$ - $\theta$  plane. Figure A.2 shows this two dimensional likelihood scan as a function of  $\theta$  and  $\mu$ , with contours overlaid, as well as the global maximum log likelihood (the minimum *negative* log likelihood). The plot also shows the maximum likelihood as a function of  $\mu$  with a red line. Equivalently, this gives the nuisance parameter value that maximizes the likelihood for a fixed  $\mu$ .

From the two dimensional scan, we see the maximum global likelihood occurs when

Figure A.2: Two dimensional likelihood scan as a function of  $\theta$  and  $\mu$ . The red line shows the maximum likelihood for a given  $\mu$ .

the signal strength parameter  $\mu$  is 1.27. This roughly makes sense given the histogram templates which had 5 signal, 4 background, and 11 observed events in the last bin. This bin dominates the result due to the strong signal presence. With the fitted signal strength,  $5 \times 1.27 + 4 \approx 11$ .

For lower values of  $\mu$ , the best likelihood values occur for increasing  $\theta$ . This can be understood as a compensatory effect: when signal yields decrease, in order to have background+signal match data, we need to “borrow” some yields from the background nuisance, which pulls up yields at higher number of jets. Of course, there is a likelihood penalty to this due to the  $p(\theta)$  term.

Figure A.3 shows two curves of  $-\ln \mathcal{L}(\mu, \theta)$  for two slices of the scan ( $\mu = \hat{\mu}$ , and  $\mu = 0$ ).

Figure A.3: Negative log likelihood as a function of  $\theta$  for  $\mu$  fixed to 0 and  $\hat{\mu}$

Let's define the LHC profiled test statistic  $q_\mu$  as

$$q_\mu = q(\mu) = -2 \ln \frac{\mathcal{L}(\mu, \hat{\theta}_\mu)}{\mathcal{L}(\hat{\mu}, \hat{\theta})} \quad (\text{A.4})$$

where  $\hat{\theta}_\mu$  is the  $\theta$  that maximizes  $\mathcal{L}$  for a particular  $\mu$ . The pair  $\hat{\mu}$  and  $\hat{\theta}$  are the ones that globally maximize the likelihood. Thus, the denominator is a single number (the global extremum of the 2-dimensional likelihood scan). The numerator is a 1-dimensional function which gives the maximum likelihood as a function of  $\mu$ . We have “profiled out” the nuisance parameter  $\theta$ . Bear in mind the additional minus sign gymnastics we must do when switching between log likelihood and negative log likelihood:

$$q_\mu = 2 \left[ \text{NLL}(\mu, \hat{\theta}_\mu) - \text{NLL}(\hat{\mu}, \hat{\theta}) \right] \quad (\text{A.5})$$

Or,  $q_\mu$  is calculated as twice the difference of the negative log likelihood values along the

red curve from the two dimensional scan, and the global minimum negative log likelihood from the same scan. Figure A.4 shows a plot of  $q_\mu = q(\mu)$

Figure A.4: LHC test statistic as a function of  $\mu$

Given this curve, we can identify the significance of the the data from one point. That is, how statistically significant would it be if just the background fluctuated to look like background+signal:

$$\sigma_{\text{obs}} = \sqrt{q_0} \quad (\text{A.6})$$

And more generally, we can compute  $1\sigma$ ,  $2\sigma$ ,  $3\sigma$ , etc. confidence bands on the fitted value of  $\hat{\mu}$  by drawing lines at  $q_\mu = 1, 4, 9, \dots$ . Why these values in particular? We turn to a normal distribution with a pdf of

$$f(x|\mu, \sigma) = \frac{1}{\sqrt{2\pi}\sigma} e^{-\frac{(x-\mu)^2}{2\sigma^2}} \quad (\text{A.7})$$

Identifying this as a likelihood pdf and ignoring all constant/offset terms independent of

$\sigma$  and  $\mu$ , then

$$q_\mu = -2 \ln(f) = 2 \frac{(x - \mu)^2}{2\sigma^2} \quad (\text{A.8})$$

We want  $x \rightarrow \mu + k \cdot \sigma$  and  $k$  is  $1, 2, 3, \dots$ , so

$$q_\mu \rightarrow \frac{(k\sigma)^2}{\sigma^2} = k^2 \quad (\text{A.9})$$

In this toy example, based on Figure A.4, the observed significance of the result is  $3.09\sigma$  and the fitted signal strength,  $\mu$ , is approximately  $1.3^{+0.4}_{-0.5}$ .
